Hand-in Devivative pricing. Gustaf Sundell, gu01475u-s.

The rightmost inequality simplifies to

$$e^{-r(T-t)}K\left(\left(\sum_{i=1}^{n}C_{i}S_{i}^{*}(T)\right)-K\right)^{\frac{1}{2}}\leq e^{-r(T-t)}K$$

$$=\sum_{i=1}^{n}C_{i}\left(\left(\sum_{i=1}^{n}C_{i}S_{i}^{*}(T)\right)-K\right)^{\frac{1}{2}}\leq e^{-r(T-t)}K$$

$$=\sum_{i=1}^{n}C_{i}\left(\left(\sum_{i=1}^{n}C_{i}S_{i}^{*}(T)\right)-K\right)^{\frac{1}{2}}\leq e^{-r(T-t)}K$$

$$=\sum_{i=1}^{n}C_{i}\left(S_{i}^{*}(T)-K\right)^{\frac{1}{2}}, \text{ which is due to}$$

$$=\sum_{i=1}^{n}C_{i}\left(S_{i}^{*}(T)-K_{i}^{*}(T)\right)^{\frac{1}{2}}, \text{ which is due to}$$

$$=\sum_{i=1}^{n}C_{i}\left(S_{i}^{*}(T)-K_{i}^{*}(T)\right)^{\frac{1}{2}}, \text{ which is due to}$$

$$=\sum_{i=1}^{n}C_{i}K_{i}^{*}=K.$$
Furthermore, as all $C_{i}\geq 0$ and $\sum_{i=1}^{n}C_{i}=1$, this means that $C^{T}X$ for some $X\in\mathbb{R}^{n}$ and with $C=\sum_{i=1}^{n}C_{i}$ is a convex combination of the

elements in X. let $X_i = S_i(T) - K_i$. so what we are comparing is $E((cTx)^{\dagger})$ fo $E(c^{T}(x)^{\dagger})$, alt. $c^{T}(E((x))^{\dagger})$

(linearity of E => where we put it doesn't seem to important here, but open for suggestions.

now, let $f(y) = (y)^{+} = \max(y, 0)$ max is a convex function, And by the definition of comexity:

f comex => f(0x, + (1-0)x2) 30f(x,)+(1-0)f(x2)

where of [0,1]
this generalises to bigger connex combinations,
of which ctx is an example, so

f(cTX) \le CTf(X), proving the Vightmest ineq.

Sorry no time for the left most ineq!

- () for this, I simulate ln (S(T)) (vector-value). and put $R = C^T ln(S(T))$ and further obtain $\Phi(T) = (e^R - K)^T$ then obtain the price as e (T-t), E (D(T)), where the expectation is estimated as mean of Simulations.
- This task was very similar, except the payoff for each simulated asset of course Was (6,(7)- K), further the price was obtained as the meanotall n=12 prices.
- 3) With the crude mc method, this was not so different from the 2 previous tasks, as well as the lab earlier this well. However, to use the control variate, the hollowing

sheme was used.

Re-using some of the previously mentioned notation, we have that the vector SLT) follows a vertor valued BBM as:

$$l = las(T) = ln(s(t)) + (v \cdot I_n - diag(ss^*)/2)(T-t) + ...$$

where G~ Nn (0,1)

this means that

and

and
$$R = CTL \Rightarrow R$$
 is also Gaussian (since it's a linear comb. of Gaussians) with

$$E(R) = c^T E(l)$$

$$Var(R) = c^{T}Var(l)c$$
,

NOW: Since
$$\frac{u}{11}(S_i(T))^{C_i} = e^{R}$$

this simplifies to a log-normal random variable

of $R = e^{R}$, $R \sim N(\mu, \sigma^2)$ then

so, using e^R as a control variate is easy, because we know the Expected value. The implementation in matlab is heavily borrowld from Lecture 10.

6

Note, as $\frac{\text{each}}{75}$; is assumed to follow a GBM, we have that if we have the vector l where $l_i = ln\left(\frac{5:(\tau)}{5:(\sigma)}\right)$ then

l = (rIn - diag(o5*)/z)(T-t) + 51T+1.6, with 6 c o as before (note we now have a given p-matrix).

the simulation then becomes:

in the

$$\widehat{PY} = \frac{1.1e^{V(T-t)}}{mean((c^Te^l-1)^+)} \approx 0.72.$$

b) Using the estimated for the price is simply calculated. I was a bit unsure it price at t=1 should still be compared to si(0) or to Si(1). I opted for the latter:

 $\widehat{\Pi}_{i} = \widehat{e}^{r(T-t)} \cdot NA \cdot \left(1 + \widehat{pr} \cdot E\left(\left(\frac{N}{2} i, \frac{S(T)}{S(I)} - 1\right)^{\frac{1}{2}}\right) \approx 108.9.$ where again S: (11 S; mplifies away,
